

# Vapor pressure deficit

## Definition

The vapor pressure deficit  $\Delta e$  is the difference between saturation  $e_s$  and actual vapor pressure  $e_a$

## Formula

The vapor pressure deficit  $\Delta e$  [kPa] can be calculated using temperature and relative humidity as follows (cf. [Allen et al. 1998](#)):

$$\Delta e = e_s - e_a$$

with

$$e_s = 0.6108 \cdot e^{\frac{17.27 \cdot T}{T+237.3}}$$

and

$$e_a = e_s \cdot \frac{H}{100}$$

where  $T$  is temperature [ $^{\circ}\text{C}$ ] and  $H$  [%] relative humidity.

However, using mean air temperature as above results in a lower estimate of  $e_s$ , thus in a lower vapor pressure deficit. It would therefore be more appropriate to use, if available, maximal and minimum temperature for calculating  $e_s$ , as follows ([Allen et al. 1998](#)):

$$e_s = \frac{1}{2} \left( 0.6108 \cdot e^{\frac{17.27 \cdot T_{max}}{T_{max}+237.3}} + 0.6108 \cdot e^{\frac{17.27 \cdot T_{min}}{T_{min}+237.3}} \right)$$

where  $T_{max}$  is maximal temperature [ $^{\circ}\text{C}$ ] and  $T_{min}$  minimal temperature [ $^{\circ}\text{C}$ ].

NB: The conversion between kiloPascals and millimeters of mercury is as follows: 1 [kPa] = 7.500616827042 [mmHg]
